1. Introduction

This paper is dedicated to turbulence-model consistent universal wall-functions for aerodynamic flows with separation, which allow for a considerable solver acceleration and reduction of memory consumptions at only a small loss in accuracy even in flows with separation and reattachment. A major concern in industrial CFD are still the huge computing costs for 3D flow simulations in complex geometries, in particular for unsteady calculations. Moreover, the increasing usage of CFD-solvers as part of optimization processes requires fast CFD-solutions. Wall-functions use near-wall modelling thereby avoiding the resolution of the strong gradients of the solution very close to the wall, and the number of boundary-layer nodes and the numerical stiffness can be reduced significantly.

The major short-coming of standard wall-functions, being based on the log-law, is that the underlying grid requirement $y^+(1) > 50$ ceases to be valid inevitably in flows with separation, as $y^+(1)$ goes to zero at the separation point and becomes small in regions of separated flow. Therein, denote $y^+(1) = y(1)u_r/\nu$ the distance of the first node above the wall in viscous length-scales, where $y(1)$ is the wall distance, $u_r$ is the friction velocity and $\nu$ is the viscosity. Historically, the first improvement over standard wall-functions was to use a so-called hybrid formulation, which are approximative velocity profiles for the entire near-wall region down to the wall. Hybrid wall functions are algebraic models (e.g. the model by Spalding) for the near-wall region ad hoc patched with the one- resp. two-equation turbulence model for the global (outer) flow. This turbulence model inconsistency causes a grid (i.e., $y^+(1)$)-dependent spreading of the solution, in particular for $c_p$ and $c_f$.

This grid-dependence is one major reason for poor predictions of flows with separation. An initially high-Re grid with $y^+(1) \approx 50$ remote from the separation point becomes more and more a low-Re grid when approaching separation. Each change in $y^+(1)$ gives a small modelling error, which is accumulated and thus may lead to poor predictions near separation and reattachment.

Hence the second crucial modification was to devise universal wall-functions which are consistent with the turbulence model of the global (outer) flow, as revealed first by [1]. Such wall-functions are based on the universality of the near-wall RANS solutions for each given one- resp. two-equation model in zero-pressure gradient (ZPG) turbulent boundary layer flows. However, for successful application to non-equilibrium flow situations appearing in aerodynamic flows, the boundary treatment of the turbulence quantities deserves special attention [2].

This paper is organized as follows: Section 2. gives the governing equations for compressible fluid flow and RANS turbulence modelling. Section 3. describes the wall-function method. In Section 4. the method is applied to a boundary layer flow at zero-pressure gradient and to 2D airfoil flows with separation.

2. RANS equations for turbulent compressible flow

We consider the steady-state Favre-averaged compressible Navier-Stokes equations in a bounded Lipschitz domain $\Omega \subset \mathbb{R}^d$ ($d = 2, 3$) with the eddy-viscosity assumption for the Reynolds-stress tensor and
the gradient-diffusion approximation for the turbulent heat-flux vector in conservative form

\[- \int_{\partial V} \mathbf{F} \cdot \mathbf{n} dS + \int_{\partial V} \mathbf{F}_v \cdot \mathbf{n} dS = 0\]

where \( V \) is an arbitrary control volume with closed boundary surface \( \partial V \), and \( \mathbf{n} \) is the unit normal vector in outward direction. The vector of conservative variables \( \mathbf{W} \), and the convective and viscous flux tensor \( \mathbf{F} \) and \( \mathbf{F}_v \), resp. are given by

\[
\mathbf{W} = \left( \begin{array}{c}
\rho \\
\rho \mathbf{u} \\
\rho E
\end{array} \right), \quad \mathbf{F} = \left( \begin{array}{c}
\rho \mathbf{u} \\
\rho \mathbf{u} \otimes \mathbf{u} + \rho \mathbf{u} \\
\rho E \mathbf{u} + p \mathbf{u}
\end{array} \right), \quad \mathbf{F}_v = \left( \begin{array}{c}
0 \\
\mathbf{T} \\
\mathbf{T} \mathbf{u} - \mathbf{q}
\end{array} \right)
\]

where \( E = c_s \theta + \frac{1}{2} \mathbf{u}^2 \) is the total specific energy. The pressure is given by \( p = (\gamma - 1) \rho (E - \frac{1}{2} \mathbf{u}^2) \).

Strain rate tensor \( \mathbf{T}(\mathbf{u}) \) and heat-flux vector \( \mathbf{q} \) are given by

\[
\mathbf{T}(\mathbf{u}) = \mathbf{S}(\mathbf{u}) - \frac{1}{3} \mathbf{\nabla} \cdot \mathbf{u} \mathbf{I}, \quad \mathbf{S}(\mathbf{u}) = \frac{1}{2} \left( \mathbf{\nabla} \mathbf{u} + (\mathbf{\nabla} \mathbf{u})^T \right), \quad \mathbf{q} = - \kappa \mathbf{\nabla} \theta
\]

with effective viscosity \( \mu_e = \mu + \mu_t \) and effective thermal conductivity \( \kappa_e = \kappa + \kappa_t \). The turbulent viscosity \( \mu_t \) is computed using a turbulence model of Spalart-Allmaras type [3] or of k-\( \omega \) model [4] and for \( \kappa_t \) the concept of a turbulent Prandtl number is used.

In order to remedy the numerical problems associated with the no-slip boundary condition, we prescribe no-penetration and the tangential component of the wall-shear stress at solid walls, where we use the approximative relation

\[
\mathbf{T} \cdot \mathbf{n} = (\mathbf{I} - \mathbf{n} \otimes \mathbf{n}) \mathbf{T} \cdot \mathbf{n} + \mathbf{n} \otimes \mathbf{n} \mathbf{T} \cdot \mathbf{n} \approx - \tau_w \mathbf{v}_t, \quad \mathbf{v}_t = \frac{1}{2} \left( \mathbf{\nabla} \mathbf{u} + (\mathbf{\nabla} \mathbf{u})^T \right)
\]

where \( \mathbf{v}_t \) is the wall-tangential component of the velocity vector at the first node above the wall located at the matching boundary \( \Gamma_\delta \), and \( \tau_w \) is the magnitude of the wall-shear stress which is computed using a wall-function method, which is described in the next section.

### 3. Turbulence-model consistent universal wall-functions for RANS turbulence modelling

Wall-functions are based on the assumption that the near-wall flow between the wall and \( \Gamma_\delta \) is described by the one-dimensional boundary layer equation. It is well-known that for equilibrium boundary layers, e.g., the flow over a flat plate at zero pressure gradient (ZPG), in the region between the wall and the outer edge of the logarithmic layer, the profiles for mean flow \( u \) and turbulence quantities \( k, \omega, \mathbf{v} \) and hence \( \nu_t \) are universal, i.e., they collapse when scaled with friction velocity \( u_f \) and viscosity \( \nu = \mu / \rho \)

\[
\frac{u^+}{u_f}, \quad \frac{y^+}{\nu}, \quad \frac{\nu_t^+}{\nu}, \quad \frac{p^+}{\rho u_f^3}, \quad \frac{k^+}{u_f^2}, \quad \frac{\omega^+}{\nu u_f^2}
\]

A universal wall-function method is called consistent w.r.t. the specific turbulence model used for the global flow, if the low-Re RANS solution for a flat-plate zero-pressure gradient boundary layer flow also solves the 1D boundary layer equation which determines the wall-function solutions, viz.,

\[
(1 + \nu_t^+ y^+ \frac{d \nu_t^+}{dy^+}) = 1 \quad \text{in} \quad (0, y_\delta^+)
\]

This implies \( \nu_t^+ = \nu_t \), i.e., wall functions have to be turbulence-model specific, as revealed by [1]. Consistency ensures that \( u = u_f^+ \) in the entire near-wall region \( \Omega_\delta \). Then predictions for surface transfer coefficients like \( c_p, c_f \) are independent of the location of the matching boundary \( \Gamma_\delta \). In contrast, the grid-dependent spreading of standard hybrid wall-functions is shown in in Figure 4 (right).
solution-fitted basis functions, viz., the wall-law by Spalding and the law by Reichardt. These may be viewed as an interpolation of the ZPG RANS solutions using a combination of two suitable zero-pressure gradient (ZPG) boundary layer almost collaps, see [2], it is sufficient to determine one new wall-law for the turbulence frequency $\omega$ in the $k$-$\omega$ turbulence model. Moreover, for $\omega$ appearing the $k$-$\omega$ model the following wall-function is proposed, see Figure 1 (right) for the magnitude of the wall-parallel velocity at $y^+$ from the global RANS solution of the previous iteration cycle and denoting $u_{\delta}$ the thickness of the visc. sublayer $\delta$, which can be solved for $u_{\delta}$ using Newton’s method. Then we set $\tau_{\delta}^{bl} = \rho u_{\delta}^2$ to be imposed as wall boundary condition for the global RANS problem (2) in the next iteration step.

3.1. New proposal for closed-form turbulence model specific wall functions

As the near-wall profiles of different versions of the Spalart-Allmaras model resp. the $k$-$\omega$ model in zero-pressure gradient (ZPG) boundary layer almost collaps, see [2], it is sufficient to determine one model-consistent universal wall-function for the Spalart-Allmaras model and one for the $k$-$\omega$ model. These may be viewed as an interpolation of the ZPG RANS solutions using a combination of two suitable solution-fitted basis functions, viz., the wall-law by Spalding and the law by Reichardt:

$$F_{\text{SA},a} = (1 - \phi_{\text{SA}})F_{\text{SP},5} + \phi_{\text{SA}}F_{\text{RE},n}, \quad \phi_{\text{SA}} = \tanh(\arg^2), \quad \arg = y^+/24 \quad (4)$$
$$F_{k\omega,a} = (1 - \phi_{k\omega})F_{\text{SP},3} + \phi_{k\omega}F_{\text{RE},n}, \quad \phi_{k\omega} = \tanh(\arg^2), \quad \arg = y^+/50 \quad (5)$$

which are plotted in Figure 1 (left). Therein, we use Reichardt’s law of the wall

$$u^+ = F_{\text{RE}}(y^+) , \quad F_{\text{RE}}(y^+) \equiv \frac{\ln(1 + 0.4y^+)}{\kappa} + 7.8 \left( 1 - e^{-\frac{y^+}{11.0}} - e^{-\frac{y^+}{3.1}} \right) . \quad (6)$$

and use the fact that Reichardt’s law blended with the classical log-law $F_{\text{log}} = \ln(y^+)/\kappa + 5.1$ gives an excellent agreement in the log-layer when using the formula

$$F_{\text{RE},i,n} = (1 - \phi_{\text{b1}})F_{\text{RE}} + \phi_{\text{b1}}F_{\text{log}}, \quad \phi_{\text{b1}} = \tanh(\arg^4), \quad \arg = y^+/27. \quad (7)$$

Spaldings law with parameter $N \in \{3, 4, 5\}$ is given by the inverse formula

$$y^+ = F^{-1}_{\text{SP},N}(u^+), \quad F^{-1}_{\text{SP},N}(u^+) \equiv u^+ + e^{-\kappa 5.2} \left( e^{\kappa u^+} - \sum_{n=0}^{N} \frac{(\kappa u^+)^n}{n!} \right) . \quad (8)$$

Then given $\bar{u}$ on $\Gamma_\delta$ from the global RANS solution of the previous iteration cycle and denoting $u_{\delta}$ the magnitude of the wall-parallel velocity at $\Gamma_\delta$, the matching condition $u_{\delta}^{bl} = u_{\delta}$ on $\Gamma_\delta$ and $u_{\delta}^{bl} = u_\tau F(yu_\tau/\nu)$ imply

$$F\left( \frac{yu_\tau}{\nu} \right) = \frac{u_{\delta}}{u_\tau} \quad \text{resp.} \quad F^{-1}\left( \frac{u_{\delta}}{u_\tau} \right) = \frac{yu_\tau}{\nu} \quad (9)$$

which can be solved for $u_{\tau}$ using Newton’s method. Then we set $\tau_{\delta}^{bl} = \rho u_{\delta}^2$ to be imposed as wall boundary condition for the global RANS problem (2) in the next iteration step.

Moreover, for $\omega$ appearing the $k$-$\omega$ model the following wall-function is proposed, see Figure 1 (right)

$$\omega = \phi \omega_{\delta} + (1 - \phi) \omega_{b2}, \quad \phi = \tanh(\arg^4), \quad \arg = y^+/10 \quad (10)$$
where we use the following blending formula and the asymptotic relations

\[
\omega_{h1} = \omega_{vis} + \omega_{log}, \quad \omega_{h2} = \left(\omega_{vis}^{1.2} + \omega_{log}^{1.2}\right)^{1/2}, \quad \omega_{vis} = \frac{6
u}{\beta_k y^2}, \quad \omega_{log} = \frac{u_*}{\sqrt{\beta_k log y}}.
\]

with constants \(\beta_k, \beta_\omega\) stemming from the transport equation for \(\omega\)

\[
\nabla \cdot (\rho u \omega) - \nabla \cdot \left((\mu + \sigma_\omega u_k) \nabla \omega\right) = 2\gamma \rho \nabla (\vec{u}) : \nabla \vec{u} - \beta_\omega \rho \omega^2
\]

(11)

### 3.2. Near-wall behaviour of turbulence quantities in non-equilibrium flow situations

The aim is to apply wall-functions to aerodynamics flows which are characterised by a locally large departure from the assumption of equilibrium flow. Then the term \(p^+\) in the original right hand side \(1 + p^+\) of (3) causes a departure from the universal profiles which becomes more pronounced as \(p^+\) increases. We consider the boundary layer flow with adverse pressure gradient devised by [1]. A detailed discussion can be found in [2]. The flat plate has length \(L = 9m\), \(u_\infty = 78ms^{-1}\) and \(\nu_\infty = 1.5 \times 10^{-6}m^2s^{-1}\). At distance \(y = 0.5m\), suction and blowing is imposed by prescribing the wall-normal velocity component \(v(x) = A \exp(-b(x-x\alpha)^2) - A \exp(-b(x-x\beta)^2)\) with \(x_\alpha = 2.5, x_\beta = 5.5, A = 0.35x, b = 108/6^2\), which produces a streamwise pressure gradient leading to separation.

For the SA-E model, the region occupied by the universal ZPG solution in reduced progressively, see Figure 2 (left), whereas \(\tilde{u}\) shows a much larger deviation from the universal ZPG solution than would be expected from the behaviour of the \(u^+\)-profiles, see Figure 2 (right). Figure 3 shows the profiles for \(k^+\) and \(\omega^+\). For \(\omega\) a progressive reduction of the region of validity of the universal ZPG solution is observed, whereas for \(k\) a general breakdown of the ZPG solution in the entire near-wall region can be seen. This causes the general breakdown of the universal ZPG solution for \(u^+\) for the SST \(k-\omega\) model, see Figure 4 (left).

From these results, the following implications for the near-wall treatment of the turbulence quantities may be drawn. From Figure 3 (right) we see that prescribing \(\omega\) also at \(\Gamma_\delta\) does not lead to a model-inconsistency for large \(p^+\)-values at least for \(y^+(1) < 10\). On the other hand, \(k\) and \(\tilde{v}\) exhibit a large departure from the universal solution in the entire near-wall region. Therefore off-wall boundary conditions, i.e., prescribing \(k\) and \(\tilde{v}\) on \(\Gamma_\delta\) based on the ZPG profile, are avoided. Instead homogeneous Dirichlet conditions are imposed on \(\Gamma_\omega\). Finally, regarding the boundary condition of \(\omega\), we mention that two treatments are popular in CFD solvers, viz., \(\omega = \omega_\delta\) on \(\Gamma_\delta\) with \(\omega_\delta = \frac{6 u}{(\beta_\omega y_\delta^2)}\) (Wilcox b.c.) and (ii) \(\omega = 10 \omega_\delta\) on \(\Gamma_\omega\) (Menter b.c.). We remark that Wilcox b.c. was found to be significantly superior in giving grid-independent wall function results, see [2] for more details.
4. Numerical results

4.1. Numerical method

The numerical results are obtained using the DLR TAU-code, which is an unstructured finite-volume solver of cell-vertex type. A central scheme with artificial scalar dissipation is used for the inviscid fluxes. The arising fixed-point problem is iterated in fictitious pseudo-time using a low-storage k-stage Runge-Kutta scheme by Jameson, see also [2] and references therein.

4.2. Flat plate turbulent boundary layer at zero pressure gradient

The ability of the new wall function proposal to give solutions almost independent of the wall-normal grid spacing is studied for the boundary layer flow at zero pressure gradient (ZPG) Flow 1400 [5] with $u_{\infty} = 33 \text{ms}^{-1}$, $\nu = 1.51 \times 10^{-5} \text{m}^2\text{s}^{-1}$ and the length of the plate is $l = 5 \text{m}$. Figure (4) (right) shows the relatively large deviation from the low-Re solution for inconsistent wall-functions if $y^+(1) \in (5, 25)$. Figures 5-6 show the almost grid independent predictions for $C_f(x)$ and $u^+(y^+)$ for the SA-Edwards (SA-E) model and for the Menter baseline $k$-$\omega$ model [4].

4.3. Application to airfoil flows

First we apply the method to the transonic airfoil flow RAE-2822 case 10 with shock induced separation at $Ma = 0.75$, $Re = 6.2 \times 10^6$ and $\alpha = 2.8^\circ$ studied experimentally in [6]. We use a series of grids of...
Figure 5: Almost grid-independent prediction of $C_f$ for ZPG flow [5] using analytical model-consistent wall-function Eq. (4) for SAE model (left) and Eq. (5) for Menter baseline model (right).

Figure 6: Velocity profiles for ZPG flow [5] for SA-E model (left) and Baseline $k$-$\omega$ model (right).

O-type with $y^+(1)$ varying from one to 60. Figures 7-8 show that for the SST $k$-$\omega$ model, the predictions for $c_p$ and $C_f$ are remarkably grid-independent, in particular regarding the shock position.

Secondly, the wall-function method is applied to the subsonic flow around the "A-airfoil" in highlift configuration at $Ma = 0.15$, $Re = 2.0 \times 10^6$, and $\alpha = 13.3^\circ$, studied experimentally in [7]. In contrast to the experiment, the airfoil surface is treated here fully turbulent. On the upper side of the airfoil, the strong adverse pressure gradient causes the turbulent boundary layer to separate close to the trailing edge. The $y^+(1)$-distributions for the series of O-type grids are shown in Figure 9. For the SST $k$-$\omega$ model with Wilcox b.c., on all grids the agreement in $c_f$ (and hence in the separation point) with the low-Re solution is remarkably good, in particular for $y^+(1) \leq 10$, see Figure 10. Figure 11 shows details of the streamtraces in the recirculation region near the trailing edge for the SST model with results on the $y^+(1) = 40$-grid being close to the low-Re solution.

5. Conclusions

A turbulence model specific wall-function method for RANS turbulence modeling of SA- and $k$-$\omega$ type has been presented which uses a boundary treatment for the turbulence quantities which is motivated by an investigation of the near-wall solutions in non-equilibrium flow situations. This approach was demonstrated to give very promising results for airfoil flows with separation.
